Tetanus with multiple wedge vertebral collapses: A case report in a 13 year old girl

Nte A R
Gabriel-Job N

Abstract Data from the case records of a 13 year old Junior Secondary School Class two girl managed at the Department of Paediatrics of the University of Port Harcourt Teaching Hospital were extracted for presentation to highlight vertebral collapse as an uncommon complication of paediatric tetanus and the associated management challenges.

The girl presented with complaints of back pains-11 days, inability to open her mouth- 9 days, jerking of the body- 8 days and upper back swelling-6 days following bruises from corporal punishment in her school. She was diagnosed to have tetanus with vertebral collapses of T3-T6. Tuberculosis and other causes of vertebral collapse were excluded. The tetanus was successfully treated but she left against medical advice and defaulted from follow-up for the management of the vertebral collapses. Poverty, ignorance and belief in traditional health care were major obstacles to her management.

Key words: Multiple wedge vertebral collapses in tetanus

Introduction

Tetanus occurs when spores of C. tetani gain access into tissues usually through puncture wounds or lacerations. In developing countries, post-neonatal tetanus is associated with traumatic injury, often a penetrating wound inflicted by dirty objects like nails, glass, unsterilized injection needle, broom sticks, circumcision and scarification wounds. The injury itself is often trivial and in 20% of cases, there may be no wound. The spores however germinate in the wound and release tetanospasmin which is taken up into motor nerve endings and transported into the central nervous system where it binds to gangliosides. There, it blocks the release of neurotransmitters from the presynaptic inhibitory neurons resulting in reflex irritability and autonomic hyperactivity- cardinal features of tetanus. Reflex spasms develop within one to four days of the first symptoms. Spasms may be precipitated by minimal stimuli such as noise, light, or touch and last from seconds to minutes. They are painful and dangerous, and may cause laryngeal spasms, apnoea, rhabdomyolysis or fractures. Vertebral fracture from tetanus is often undiagnosed and can be mistaken for spinal tuberculosis hence the need for a high index of suspicion. Although vertebral fracture complicating tetanus has been reported among adolescents and adults in Nigeria, none has been seen among the several cases of tetanus managed in this unit for about thirty years. The diagnosis of tetanus with multiple vertebral collapses and the management challenges necessitated the current case report.

Case Report

SA, aged 13 years, presented with complaints of back pains-11days, inability to open the mouth– nine days, jerking of the body– eight days, and upper back swelling-6 days following bruises from corporal punishment in her school. She was diagnosed to have tetanus with vertebral collapses of T3-T6. Tuberculosis and other causes of vertebral collapse were excluded. The tetanus was successfully treated but she left against medical advice and defaulted from follow-up for the management of the vertebral collapses. Poverty, ignorance and belief in traditional health care were major obstacles to her management.

Significant findings on examination were an ill looking, mildly pale teenager with several spontaneous and provoked spasms, trismus, risus sardonicus, opisthotonus
showed a total white cell count of 11.5 x10^9 /l; neutrophils- 80% and lymphocytes- 20%; packed cell volume - 33% and Erythrocyte sedimentation rate- 23mm/hour (Western Green Method). Mantoux test and retroviral screening were negative. The urinalysis and electrolyte, urea and creatinine assays were normal. X-rays of the cervical spine were normal except for the straightening of the vertebrae. Thoracic spine radiographs showed kyphoscoliosis, anterior wedge collapses of T3-T6 vertebral bodies with reduction of their intervening disc spaces (Fig. 1). The other vertebrae, paraspinous soft tissues and chest were normal on X-rays and did not suggest tuberculosis.

The initial diagnosis was tetanus co-existing with tuberculosis of the spine to exclude multiple vertebral fractures complicating the tetanus. Her full blood count showed a total white cell count of 11.5 x10^9 /l; neutrophils- 80% and lymphocytes- 20%; packed cell volume - 33% and Erythrocyte sedimentation rate- 23mm/hour (Western Green Method). Mantoux test and retroviral screening were negative. The urinalysis and electrolyte, urea and creatinine assays were normal. X-rays of the cervical spine were normal except for the straightening of the vertebrae. Thoracic spine radiographs showed kyphoscoliosis, anterior wedge collapses of T3-T6 vertebral bodies with reduction of their intervening disc spaces (Fig. 1). The other vertebrae, paraspinous soft tissues and chest were normal on X-rays and did not suggest tuberculosis.

The usual presentation in tuberculosis consists of pain overlying the affected vertebrae, low-grade fever, chills,
weight loss, and nonspecific constitutional symptoms of varying duration. Paraplegia could be the first sign of spinal disease in tuberculosis. Varying degrees of weakness, nerve-root compression and sensory involvement can occur. Weight loss has been recorded in 58% of patients and 90% to 100% of patients had back pain. Neurological involvement varied in different studies from 32% to 76% with notable differences in severity. None of these features were found in our patient. Although a positive test with the Purified Protein Derivative by Mantoux method was reported in 62-95% of cases of vertebral tuberculosis, a negative test should not be considered as completely excluding tuberculosis infection. Furthermore, although, leukocytosis and elevated Erythrocyte Sedimentation Rate (ESR) of over 100 mm/h (Westergreen Method) are suggestive, our patient did not have these features. Radiographic changes associated with Pott’s disease present relatively late and plain radiographs describe changes consistent with TB spine in 91-99% of cases. Radiographs may reveal advanced lesions with vertebral osteolysis and disc space narrowing affecting more commonly the lower thoracic vertebrae than the lumbar and cervical vertebrae.

**Conclusion**

This 13 year old girl presented with active tetanus complicated by multiple wedge collapses of T3-T6. She responded to the regimen for tetanus but defaulted from treatment for the vertebral fractures. Poverty, ignorance and resort to local treatment remain barriers to successful treatment of children.
